[Variational](#page-2-0) inference

Recap: Posterior Inference for Latent Variable Models

We encountered a few latent variable models (e.g. the TrueSkill model).

These models have a factorization $p(x, z) = p(z)p(x|z)$ where:

- *• x* are the observations or data,
- *• z* are the unobserved (latent) variables
- *• p*(*z*) is usually called the prior
- $p(x|z)$ is usually called the **likelihood**
- The conditional distribution of the unobserved variables given the observed variables (aka the posterior) is

$$
p(z|x) = \frac{p(x, z)}{p(x)} = \frac{p(x, z)}{\int p(x, z) dz}
$$

• We assume $p(x) = \int p(x, z) dz$ is hard to compute

Variational inference works as follows:

- Choose a tractable parametric distribution $q_{\phi}(z)$ with parameters ϕ . This distribution will be used to approximate $p(z|x)$.
	- For example, $q_{\phi}(z) = \mathcal{N}(z|\mu, \Sigma)$ where $\phi = (\mu, \Sigma)$.
- Encode some notion of "distance" between $p(z|x)$ and $q_{\phi}(z)$ that can be efficiently estimated. Usually we will use the KL divergence.
- *•* Minimize this distance.

Measure the difference between *q* and *p* using the Kullback-Leibler divergence

$$
\text{KL}(q_{\phi}(z)||p(z|x)) = \int q_{\phi}(z) \log \frac{q_{\phi}(z)}{p(z|x)} dz = \mathbb{E}_{z \sim q_{\phi}} \log \frac{q_{\phi}(z)}{p(z|x)}
$$

Recall: Properties of the KL Divergence

- KL $(q_{\phi}||p) \geq 0$
- KL $(q_{\phi}||p) = 0 \Leftrightarrow q_{\phi} = p$
- KL $(q_{\phi} \| p) \neq$ KL $(p \| q_{\phi})$
- *•* KL divergence is not a metric, since it is not symmetric

ELBO and its [properties](#page-6-0)

- Evaluating $KL(q_{\phi}(z)||p(z|x))$ is intractable because of the integral over *z* and the term $p(z|x)$, which is intractable to normalize.
- We can still "optimize" this KL without knowing the normalization constant $p(x)$.
- We solve a surrogate optimization problem: maximize the **evidence lower bound** (ELBO); to be introduced in a second.
- *•* Maximizing the ELBO is equivalent to minimizing

 $KL(q_{\phi}(z)||p(z|x)).$

ELBO: Evidence Lower Bound

Maximizing the ELBO is the same as minimizing $KL(q_{\phi}(z)||p(z|x))$.

$$
\begin{aligned} \text{KL}(q_{\phi}(z) \| p(z | x)) &= \mathop{\mathbb{E}}_{z \sim q_{\phi}} \log \frac{q_{\phi}(z)}{p(z | x)} \\ &= \mathop{\mathbb{E}}_{z \sim q_{\phi}} \left[\log \left(q_{\phi}(z) \cdot \frac{p(x)}{p(z, x)} \right) \right] \\ &= \mathop{\mathbb{E}}_{z \sim q_{\phi}} \left[\log \frac{q_{\phi}(z)}{p(z, x)} \right] + \mathop{\mathbb{E}}_{z \sim q_{\phi}} \log p(x) \\ &:= -\mathcal{L}(\phi) + \log p(x) \end{aligned}
$$

Where $\mathcal{L}(\phi)$ is the **ELBO**:

$$
\mathcal{L}(\phi) = \mathbb{E}_{z \sim q_{\phi}} \Big[\log p(z, x) - \log q_{\phi}(z) \Big]
$$

ELBO: Evidence Lower Bound

 $Recall: KL(q_{\phi}(z)||p(z|x)) = -\mathcal{L}(\phi) + log p(x).$

• Rearranging, we get

 $\mathcal{L}(\phi) + \text{KL}(q_{\phi}(z) || p(z|x)) = \log p(x)$

• Because
$$
KL(q_{\phi}(z)||p(z|x)) \geq 0
$$
,

 $\mathcal{L}(\phi)$ < log $p(x)$

- maximizing the ELBO \Rightarrow minimizing $KL(q_{\phi}(z)||p(z|x))$.
- *•* Note: *L*(φ) = E *z*∼*q*^φ $\left[\log p(z,x)\right] + \mathop{\mathbb{E}}\limits_{z \sim q_\phi}$ $\Big[-\log q_\phi(z)\Big]$, so

 $E L B O =$ expected log -join+entropy

• Sometimes we write $\mathcal{L}(\phi|\mathbf{x})$ or $\mathcal{L}(\theta,\phi|\mathbf{x})$ if $p(z,\mathbf{x})$ depends on a parameter θ .

[Estima](#page-10-0)ting gradients of the ELBO

Maximizing ELBO

Recall: ∇*L*(φ) gives the direction of the steepest ascent of *L*(φ).

Gradient descent (GD) methods: $\phi_{t+1} = \phi_t + s_t \nabla \mathcal{L}(\phi_t)$.

- \bullet We have that $\mathcal{L}(\phi) = \mathop{\mathbb{E}}\limits_{z \sim q_\phi}$ $\left[\log p(x, z) - \log q_{\phi}(z)\right].$
- We need $\nabla_{\phi} \mathcal{L}(\phi)$ or its unbiased estimate (stochastic GD).

Approximating the gradient of some $\mathbb{E}(f(Y, \phi))$:

• If the distribution of *Y* independent of φ then

 $\nabla_{\phi} \mathbb{E}(f(Y, \phi)) = \mathbb{E}(\nabla_{\phi} f(Y, \phi)).$

- We then have $\nabla_{\!\phi} \mathbb{E}(f(Y,\phi)) \approx \frac{1}{m} \sum_{i=1}^{m} \nabla_{\!\phi} f(y_i,\phi)$.
- *•* Problem: In our case the distribution of *z* depends on φ.

The reparameterization trick

Problem:

$$
\nabla_{\phi} \mathop{\mathbb{E}}_{z \sim q_{\phi}} \Big[\log p(x, z) - \log q_{\phi}(z) \Big] \neq \mathop{\mathbb{E}}_{z \sim q_{\phi}} \Big[\nabla_{\phi} \left(\log p(x, z) - \log q_{\phi}(z) \right) \Big].
$$

In some situations there is a trick:

Suppose that $z \sim q_\phi$ has the same distribution as $T(\epsilon, \phi)$, where ϵ is a random variable whose distribution p_0 does not depend on ϕ . In this case, to sample $z \sim q_\phi$ by:

- sampling a random variable $\epsilon \sim p_0$,
- deterministically computing $z = T(\epsilon, \phi)$.

For example, if $z \sim N(\mu, \sigma^2)$ then $z = \mu + \sigma \epsilon$, where $\epsilon \sim N(0, 1)$.

• sample ∼ *N*(0*,* 1),

•
$$
\phi = (\mu, \sigma^2), \ T(\epsilon, \phi) = \mu + \sigma \epsilon.
$$

The reparameterization trick

If $z = \mathcal{T}(\epsilon, \phi)$, we can write

$$
\mathop{\mathbb{E}}_{z \sim q_{\phi}} \Big[\log p(x, z) - \log q_{\phi}(z) \Big] = \mathop{\mathbb{E}}_{\epsilon \sim p_0} \Big[\log p(x, \, \mathcal{T}(\epsilon, \phi)) - \log q_{\phi}(\, \mathcal{T}(\epsilon, \phi)) \Big]
$$

This lets us use simple Monte Carlo: $z = T(\phi, \epsilon)$

$$
\nabla_{\phi} \mathcal{L}(\phi) = \nabla_{\phi} \mathbb{E}_{z \sim q_{\phi}(z)} \Big[\log p(x, z) - \log q_{\phi}(z) \Big] \n= \nabla_{\phi} \mathbb{E}_{\epsilon \sim p_0(\epsilon)} \Big[\log p(x, T(\phi, \epsilon)) - \log q_{\phi}(T(\phi, \epsilon)) \Big] \n= \mathbb{E}_{\epsilon \sim p_0(\epsilon)} \nabla_{\phi} \Big[\log p(x, T(\phi, \epsilon)) - \log q_{\phi}(T(\phi, \epsilon)) \Big].
$$

so generating a sample $\epsilon_1, \ldots, \epsilon_m$ from p_0 , we get

$$
\nabla_{\!\phi} \mathcal{L}(\phi) \; \approx \; \frac{1}{m} \sum_{i=1}^{m} \nabla_{\!\phi} \Big[\log p(x, \, \mathcal{T}(\phi, \epsilon_i)) - \log q_{\phi}(\, \mathcal{T}(\phi, \epsilon_i)) \Big].
$$

The distribution $p(z|x)$ may be very complicated:

- *• z* are weights of neural network
- *x* are all observed outputs: y_1, y_2, \ldots Assume inputs x_i are fixed.
- *• p*(*z*) prior on weights, usually standard normal (hard to set)
- $p(x|z) = \prod_i p(y_i|x_i, z)$
	- ► for regression: $p(y_i|x_i, z) = \mathcal{N}(nnet(x_i, z), \sigma^2)$
	- ► for classification: $p(y_i|\mathbf{x}_i, z) =$ Categorical(y_i |softargmax(nnet(\mathbf{x}_i, z)))
- $p(z|\mathbf{x}, y)$ is a collection of plausible sets of parameters that all fit the data.

Note: The number of inputs/outputs may be too large for our gradient computations.

Goal: Estimate parameters θ in a latent variable model

$$
p(x_{1:N}, z_{1:N}|\theta) = \prod_{n=1}^{N} p(z_n|\theta) p(x_n|z_n, \theta).
$$

We have $\log p(x_n|\theta) = \log \left[\int p(x_n|z_n, \theta) p(z_n|\theta) dz_n \right]$, which is intractable.

Using the fact that $\mathcal{L}(\theta, \phi_n | x_n) \leq \log p(x_n | \theta)$, we can optimize θ by maximizing

$$
\mathcal{L}(\theta, \phi_{1:N}|x_{1:N}) \ := \ \sum_{n=1}^N \mathcal{L}(\theta, \phi_n|x_n) \ \leq \ \sum_{n=1}^N \log p(x_n|\theta).
$$

Variational EM (high level idea): Alternate between optimizing with respect to $\phi_{1:N}$ and θ .

Recall: $\mathcal{L}(\theta, \phi_1:\mathbb{N}|\mathbf{x}_1:\mathbb{N}) = \sum_{n=1}^{N} \mathcal{L}(\theta, \phi_n|\mathbf{x}_n)$.

- Instead of computing the full gradient with respect to θ (which is in general not possible), we compute a simple Monte Carlo estimate of it.
- For example, at each step we can draw a random minibatch of $B = |\mathcal{B}|$ examples from the dataset, and then make an approximation

$$
\mathcal{L}(\theta, \phi_{1:N}|x_{1:N}) \approx \frac{N}{B}\sum_{x_n\in\mathcal{B}}\mathcal{L}(\theta, \phi_n|x_n).
$$

(this is then optimized with respect to θ)

MCMC: Pros & Cons

Pros of MCMC:

- *•* Accurate results (at least asymptotically)
- *•* Flexibility
- *•* No approximation
- *•* Handles multimodal distributions

Cons of MCMC:

- *•* High computational cost
- *•* Requires tuning of hyperparameters
- *•* Convergence issues
- Inefficient in sampling complex dependencies

Pros of SVI:

- *•* Faster convergence
- *•* Scalability
- *•* Ease of use

Cons of SVI:

- *•* Approximate results
- *•* Limited flexibility
- *•* Mode seeking
- *•* Sensitive to choice of hyperparameters

We covered the basics of gradient-based stochastic variational inference.

More specifically:

- *•* ELBO
- *•* Reparametrization trick
- *•* Stochastic VI
- *•* Gaussian mixture models
- *•* EM-algorithm
- *•* Clustering

[Gaussian](#page-21-0) Mixture Models

We combine simple models into a complex model by taking a mixture of *K* multivariate Gaussian densities of the form:

$$
p(x) = \sum_{k=1}^K \pi_k N_m(x|\mu_k, \Sigma_k),
$$

where $\pi_k \geq 0$, $\sum_{k=1}^K \pi_k = 1$, and $N_m(x|\mu_k, \Sigma_k)$ is the *m*-dim Gaussian density.

- *•* Each Gaussian component has its own mean vector *µ^k* and covariance matrix Σ*^k* .
- *•* The parameters π*^k* are called the mixing coefficients.

Example:

- *• K* = 3 (three Gaussian components)
- *• m* = 1 (univariate Gaussians)

In 1892, scientists collected data on populations of the crab and observed that the ratio of forehead width to the body length actually showed a highly skewed distribution.

Source: *On Certain Correlated Variations in Carcinus maenas* (1893) W. F. Weldon.

They wondered whether this distribution could be the result of the population being a mix of two different normal distributions (two sub-species).

In 1894, Karl Pearson proposed a method to fit this model ([read](https://archive.org/details/philtrans02543681) here), whose modern version is the "method of moments". The method involved solving a higher order polynomial.

• Illustration of a mixture of 3 Gaussians in a 2-dimensional space:

(a) Contours of constant density of each of the mixture components, along with the mixing coefficients

(b) Contours of marginal probability density $p(\mathbf{x}) = \sum_{k=1}^{N} \pi_k \mathcal{N}(\mathbf{x} | \boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k)$

(c) A surface plot of the distribution $p(x)$.

Recall: $p(x) = \sum_{k=1}^{K} \pi_k N_m(x | \mu_k, \Sigma_k).$

- *•* Consider a latent variable *z* with *K* states *z* ∈ *{*1*, . . . ,K}*.
- *•* The distribution of *z* given by the mixing coefficients:

$$
p(z=k)=\pi_k.
$$

• Specify the conditional as $p(x|z = k) = N_m(x|\mu_k, \Sigma_k)$ with joint:

$$
p(x, z = k) = p(z = k)p(x|z = k) = \pi_k N_m(x|\mu_k, \Sigma_k).
$$

• Then the marginal *p*(*x*) satisfies

$$
p(x) = \sum_{k=1}^{K} p(x, z = k) = \sum_{k=1}^{K} \pi_k N_m(x | \mu_k, \Sigma_k).
$$

- If we have several observations x_1, \ldots, x_N , for every observed data point x_n there is a corresponding latent *zn*.
- *•* Consider the conditional *p*(*z|x*)

$$
p(z = k|x) = \frac{p(z = k)p(x|z = k)}{\sum_{j=1}^{K} p(z = j)p(x|z = j)} = \frac{\pi_{k}N_{m}(x|\mu_{k}, \Sigma_{k})}{\sum_{j=1}^{K} \pi_{j}N_{m}(x|\mu_{j}, \Sigma_{j})}
$$

• We view π_k as prior probability that $z = k$, and $p(z = k|x)$ is the corresponding posterior once we have observed the data.

• 500 points drawn from a mixture of 3 Gaussians.

Samples from the joint distribution $p(x,z)$.

Samples from the marginal distribution $p(x)$.

Same samples where colors represent the value of responsibilities.

Parameters: $\pi = (\pi_1, \ldots, \pi_K)$, $\mu = (\mu_1, \ldots, \mu_K)$, $\Sigma = (\Sigma_1, \ldots, \Sigma_K)$. $Recall: p(x | \pi, \mu, \Sigma) = \sum_{k=1}^{K} \pi_k N_m(x | \mu_k, \Sigma_k)$

- Represent the dataset $\{x_1, \ldots, x_N\}$ as $\boldsymbol{X} \in \mathbb{R}^{N \times m}$.
- *•* The latent variable is represented by ^a vector *^z* [∈] ^R*^N* .
- *•* The log-likelihood takes the form

$$
\log p(\mathbf{X}|\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\Sigma}) = \sum_{n=1}^{N} \log \left(\sum_{k=1}^{K} \pi_k N_m(x_n | \mu_k, \Sigma_k) \right)
$$

Maximum Likelihood (*µ*)

Recall:
$$
\log p(\mathbf{X}|\pi, \mu, \Sigma) = \sum_{n=1}^{N} \log \left(\sum_{k=1}^{K} \pi_k N_m(x_n|\mu_k, \Sigma_k) \right)
$$
.

• Differentiating wrt *µ^k* and setting to zero gives:

$$
0 = \sum_{n=1}^{N} \frac{\pi_{k} N(x_{n} | \mu_{k}, \Sigma_{k})}{\sum_{j} \pi_{j} N(x_{n} | \mu_{j}, \Sigma_{j})} \Sigma_{k}^{-1}(x_{n} - \mu_{k}) = \sum_{n=1}^{N} p(z_{n} = k | x_{n}) \Sigma_{k}^{-1}(x_{n} - \mu_{k})
$$

= $\Sigma_{k}^{-1} \left(\sum_{n=1}^{N} p(z_{n} = k | x_{n}) x_{n} - \mu_{k} \sum_{n=1}^{N} p(z_{n} = k | x_{n}) \right).$

• Equivalently (as Σ*^k* is positive definite)

$$
\mu_k = \sum_n \frac{p(z = k | x_n)}{N_k} x_n, \qquad N_k = \sum_n p(z = k | x_n).
$$

• Simple interpretation: the MLE given by the weighted mean of the data weighted by the posterior $p(z = k | x_n)$.

 $\text{Recall: } \log p(\boldsymbol{X} | \boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\Sigma}) = \sum_{n=1}^{N} \log \left(\sum_{k=1}^{K} \pi_k N_m(x_n | \mu_k, \Sigma_k) \right).$

• Differentiating wrt Σ*^k* and setting to zero gives:

$$
\Sigma_k = \sum_n \frac{p(z=k|x_n)}{N_k} (x_n - \mu_k)(x_n - \mu_k)^\top.
$$

- *•* Again data points weighted by posterior probabilities.
- *•* Finally, for the weights π*^k* the MLE is

$$
\pi_k = \frac{N_k}{\sum_{j=1}^K N_j} = \frac{N_k}{N}, \qquad N_k = \sum_n p(z = k | x_n).
$$

- *•* The MLE does not have a closed form solution.
- The estimates depend on the posterior probabilities $p(z = k|x_n)$, which themselves depend on those parameters.
- *•* Indeed, recall that

$$
p(z = k|x_n) = \frac{\pi_k N_m(x_n|\mu_k, \Sigma_k)}{\sum_{j=1}^K \pi_j N_m(x_n|\mu_j, \Sigma_j)}.
$$

- Iterative solution (EM algorithm):
	- \blacktriangleright Initialize the parameters to some values.

E-step Update the posteriors $p(z = k|x_n)$. M-step Update model parameters $π, μ, Σ$.

 \triangleright Repeat.

EM algorithm for Gaussian mixtures

- • Initialize π, μ, Σ .
- *•* E-step: for each *k, n* compute the posterior probabilities

$$
p(z = k|x_n) = \frac{\pi_k N_m(x_n|\mu_k, \Sigma_k)}{\sum_{j=1}^K \pi_j N_m(x_n|\mu_j, \Sigma_j)}.
$$

• M-step: Re-estimate model parameters

$$
\mu_k^{\text{new}} = \sum_{n=1}^N \frac{p(z = k | x_n)}{N_k} x_n, \qquad N_k = \sum_{n=1}^N p(z = k | x_n),
$$

$$
\Sigma_k^{\text{new}} = \sum_{n=1}^N \frac{p(z = k | x_n)}{N_k} (x_n - \mu_k^{\text{new}}) (x_n - \mu_k^{\text{new}})^\top,
$$

$$
\pi_k^{\text{new}} = \frac{N_k}{N}.
$$

• Evaluate the log-likelihood and check for convergence.

Consider a general setting with latent variables.

• Observed dataset $\mathbf{X} \in \mathbb{R}^{N \times D}$, latent variables $\mathbf{Z} \in \mathbb{R}^{N \times K}$.

Maximize the log-likelihood log $p(\mathbf{X}|\theta) = \log \left(\sum_{\mathbf{Z}} p(\mathbf{X}, \mathbf{Z}|\theta) \right)$.

- Initialize parameters θ^{old}.
- **E-step**: use θ ^{old} to compute the posterior $p(Z|X, \theta^{old})$.
- **M-step**: $\theta^{\text{new}} = \arg \max_{\theta} Q(\theta, \theta^{\text{old}})$, where

$$
Q(\theta, \theta^{\text{old}}) = \sum_{\textbf{Z}} p(\textbf{Z} | \textbf{X}, \theta^{\text{old}}) \log p(\textbf{X}, \textbf{Z} | \theta) = \mathbb{E} \Big(\log p(\textbf{X}, \textbf{Z} | \theta) \Big| \textbf{X}, \theta^{\text{old}} \Big)
$$

which is tractable in many applications.

• Replace $\theta^{old} \leftarrow \theta^{new}$. Repeat until convergence.

Example: Gaussian mixture

• If *z* was observed, the MLE would be trivial

$$
\log p(\boldsymbol{X}, \boldsymbol{Z} | \theta) = \sum_{n=1}^N \log p(x_n, z_n | \theta) = \sum_{n=1}^N \sum_{k=1}^K \mathbb{1}(z_n = k) \log \left(\pi_k N(x_n | \mu_k, \Sigma_k) \right).
$$

For the E-step: $p(\mathbf{Z}|\mathbf{X}, \theta) = \prod_{n=1}^{N} p(z_n|\mathbf{X}, \theta)$ we have

$$
p(z_n = k | \mathbf{X}, \theta) = p(z_n = k | x_n, \theta) = \frac{\pi_k N_m(x_n | \mu_k, \Sigma_k)}{\sum_{j=1}^K \pi_j N_m(x_n | \mu_j, \Sigma_j)}.
$$

For the M-step: $\mathbb{E}(\mathbb{1}(z_n = k)|\boldsymbol{X}, \theta^{\text{old}}) = p(z_n = k|\boldsymbol{X}, \theta^{\text{old}})$ and so

$$
\mathbb{E}\bigg(\log p(\boldsymbol{X},\boldsymbol{Z}|\theta)\bigg|\boldsymbol{X},\theta^{\text{old}}\bigg) = \sum_{n=1}^N\sum_{k=1}^K p(z_n=k|\boldsymbol{X},\theta^{\text{old}})\log\big(\pi_k N(x_n|\mu_k,\Sigma_k)\big).
$$

Maximizing gives the formulas on Slide [28](#page-32-0).

Relationship to K-Means (STA 314?)

- *•* Consider a Gaussian mixture, s.t. $\Sigma_k = \epsilon I$ for all $k = 1, \ldots, K$.
- *•* We have

$$
p(x|\mu_k, \Sigma_k) = \frac{1}{(2\pi\epsilon)^{m/2}} \exp\left(-\frac{1}{2\epsilon}||x - \mu_k||^2\right).
$$

- Consider the EM algorithm in this special case, $\theta = (\pi, \mu)$.
- *•* The posterior probabilities take the form

$$
p(z_n = k | \mathbf{X}, \theta) = \frac{\pi_k \exp(-\|x_n - \mu_k\|^2 / 2\epsilon)}{\sum_{j=1}^K \pi_j \exp(-\|x_n - \mu_j\|^2 / 2\epsilon)}.
$$

• If $\epsilon \to 0$, the term with smallest $||x_n - \mu_j||$ tends to zero most slowly.

• Thus
$$
p(z_n = k | \mathbf{X}, \theta) \rightarrow r_{nk} = \begin{cases} 1 & \text{if } k = \arg\min_j ||x_n - \mu_j|| \\ 0 & \text{otherwise} \end{cases}
$$

Relationship to K-Means

Recall: $\mathbb{E}(\log p(X, Z | \theta) | X, \theta^{\text{old}}) = \sum_{n=1}^{N} \sum_{k=1}^{K} p(z_n = k | X, \theta^{\text{old}}) \log (\pi_k N(x_n | \mu_k, \Sigma_k)).$

As $\epsilon \to 0$, we have

$$
p(z_n = k | \mathbf{X}, \theta) \rightarrow r_{nk} = \begin{cases} 1 & \text{if } k = \arg \min_j ||x_n - \mu_j|| \\ 0 & \text{otherwise} \end{cases}
$$

which gives

$$
\mathbb{E}\Big(\log p(\boldsymbol{X},\boldsymbol{Z}|\theta)\Big|\boldsymbol{X},\theta^{\text{old}}\Big) \rightarrow -\frac{1}{2}\sum_{n=1}^N\sum_{k=1}^K r_{nk}||x_n-\mu_k||^2+\text{const.}
$$

- In the limit, maximizing the expected log-likelihood is equivalent to minimizing the distortion measure in the K-means algorithm.
- *•* The EM-algorithm is slower but more flexible and accurate.
- *•* EM algorithm is a classical method in statistics.
- *•* It can be used in the presence of latent variables.
- When applied to Gaussian mixtures, compared to k-means, it captures the covariance structure of the data.
